By producing a train of absorption or dispersion signals (continuous-wave magnetic resonance) or free induction decays (pulsed magnetic resonance) it is possible to save time in spin-lattice relaxation measurements due to the fact that it is not necessary to wait for equilibrium magnetization before initiating the train. The relaxation time may be calculated from the train according to a simple rapidly converging iteration.

INTRODUCTION

A periodic train of magnetic field passages through resonance, or a periodic train of rf pulses at resonance produce, respectively, a corresponding train of absorption (or dispersion) signals or free induction decays, illustrated in Fig. 1; these may be analyzed to yield the spin-lattice relaxation time $T_1$. Methods and apparatus for accomplishing such experiments have been discussed for cw NMR, cw EPR, and pulsed NMR. It is the purpose of this paper to show that it is not necessary to wait for equilibrium of the spin system before initiating such a train of signals, and the resulting time saving may be considerable if $T_1$ is large.

I. THEORY

Following Look and Locker, let $\tau$ be the time between successive signals in the train and let $M_n^+$ and $M_n^-$ be, respectively, the magnetization along the magnetic field before and after the $n$th passage (or pulse). Furthermore, define the fraction of saturation, $X$, due to a passage (or pulse) by

$$M_n^+ = M_n^-(1-X), \quad 0 \leq X \leq 2,$$

where $X=2$ would correspond to an adiabatic reversal or 180° pulse. Assuming that between successive passages $M$ relaxes exponentially we have

$$M_{n+1}^- = M_e^- (1-e^{-\tau/T_1}) + M_n^- e^{-\tau/T_1}$$

$$= M_e^- (1-e^{-\tau/T_1}) + M_n^- (1-X) e^{-\tau/T_1},$$

where $M_e^-$ is the equilibrium magnetization. Designating the first signal in the train as $M_0$ and letting $u=e^{-\tau/T_1}$ and $y=(1-X)$, we can relate $M_n$ to $M_0$ by induction, according to Eq. (2),

$$M_1^- = M_e^- (1-u) + M_0^- yu$$

$$M_2^- = M_e^- (1-u) [1+yu] + M_0^- y^2 u^2$$

$$\vdots$$

$$M_n^- = M_e^- (1-u) [1+yu+y^2 u^2 \cdots y^{n-1} u^{n-1}]$$

$$+ M_0^- y^n u^n. \quad (3)$$

The observed signal $M_n$ will be proportional to $M_n^-$ so we can drop the superscripts and rewrite Eq. (3) as

$$M_n = M_e (1-u) \sum_{q=0}^{n-1} y^q u^q + M_0 y^n u^n$$

$$= M_e (1-u) \frac{1-y^n u^n}{1-yu} + M_0 y^n u^n. \quad (4)$$

After many passages, the magnetization reaches a constant value $M_\infty$ given by Eq. (4) as

$$M_\infty = M_e (1-u)/(1-yu) \quad (5)$$

and, thus,

$$M_\infty - M_0 = (M_\infty - M_0) [(1-X)e^{-\tau/T_1}]^n. \quad (6)$$

---

Taking logarithms of both sides gives an equation of the form \( Y = I + nS \) where \( I \) and \( S \) are, respectively, the intercept and slope of a \( Y \) vs \( n \) plot. Here

\[
Y = \ln(M_n - M_\infty) \quad (8a)
\]

or, using Eq. (5) to solve for \( X = 1 - y \),

\[
(M_n - M_\infty) = (M_0 - M_\infty) \left[ e^{-\tau/T_1} \left( 1 + \frac{M_\infty - M_n}{M_\infty} \right) \right].
\] (7)

From this, we use Eq. (5)

\[
e^{-\tau/T_1} = \frac{1 - (1-e^S)\frac{M_n}{M_\infty}}{1 - e^S}.
\] (12)

which can be solved for \( T_1 \) using the experimental parameters, \( \tau \) and \( T \), those given by the data, \( M_\infty \) and \( M_0 \), and the calculated slope \( S \) of an In\((M_n - M_\infty)\) vs \( n \) plot.

## II. Iteration

It is generally more convenient to solve Eq. (12) iteratively if \( T \geq T_1 \) since the second term in square brackets is clearly a corrective term which is small when \( T \) is large, making \( M_0 \) close to \( M_\infty \). Thus, defining the successive approximations to \( T_1 \) as \( T_1^{(1)}, T_1^{(2)}, T_1^{(3)}, \ldots \), we cyclically solve

\[
e^{-\tau/T_1^{(n+1)}} = 1 - (1-e^S)\frac{M_n}{M_0}\left[ 1 - C^{(n)} \right], \quad n \geq 0
\] (13a)

\[
C^{(n)} = (1-e^S)e^{\tau/T_1^{(n)}}/(1-e^S), \quad n \geq 1
\] (13b)

letting \( C^{(0)} = 0 \). The first few terms are

\[
e^{-\tau/T_1^{(1)}} = 1 - (1-e^S)\frac{M_n}{M_0}
\] (14a)

\[
C^{(1)} = (1-e^S)e^{\tau/T_1^{(1)}}/(1-e^S)
\] (14b)

\[
e^{-\tau/T_1^{(2)}} = 1 - (1-e^S)\frac{M_n}{M_0}(1-C^{(1)})
\] (14c)

The convergence is generally quite rapid. In one example \((^{19}\text{F in CaF}_2)\), which the authors chose at random, the parameters were \( T_1 = 0.125 \text{ sec} \) (true \( T_1 \)), \( e^S = 0.688 \), \( \tau = 0.025 \text{ sec} \), \( M_\infty/M_0 = 0.675 \), and \( T = 0.164 \pm 0.357 \text{ sec} \). Then, using Eqs. (13a) and (13b), we got \( T_1^{(1)} = 0.106 \text{ sec} \), \( T_1^{(2)} = 0.122 \text{ sec} \), \( T_1^{(3)} = 0.124 \text{ sec} \), and \( T_1^{(4)} = 0.125 \text{ sec} \). Thus, with only three iterations the \( T_1 \) value was within 1% of the correct value and the data accumulation time was only about one half of that required to insure \( M_0 = M_\infty \). In another example \((^1\text{H in H}_2\text{O})\) the parameters were \( T_1 = 2.50 \text{ sec} \), \( e^S = 0.580 \), \( \tau = 0.0625 \text{ sec} \), \( M_\infty/M_0 = 0.0974 \), and \( T = 2.23 \text{ sec} \). The iterations gave \( T_1^{(1)} = 1.49 \text{ sec} \), \( T_1^{(2)} = 2.48 \text{ sec} \); thus, after seven iterations the \( T_1 \) value was less than 1% low and the data accumulation time was only about one fourth that required.

Although in the above examples the \( T_1 \) measurement time would not be long by any method, it is apparent that if it is expected to be long, due to a large \( T_1 \), the method described in this paper has significant advantages since it is not necessary to wait for spin system equilibrium before taking data. The iterations are easily programmed on a computer.
